Frenectomy review: conventional techniques with diode laser

Authors: Dr M.L.V. Prabhujai, Prof Dr S.S. Madhu Preetha, Dr Ameya G. Moghe, India

Introduction
The word frenum is derived from the Latin word “frenum”. Frenectomy is the removal of the single-shaped folds found in the maxillary and mandibular alveolar mucosa, and located between the central incisors and canine premolar area. Frenum may be classified depending upon the attachment level, and classified as: Long and thin

Short and broad. Depending upon the attachment level, frenum has been classified as:

- Plaque & Schuchardt Z-plasty.
- These include Dieffenbach, conventional frenectomy technique.
- Conventional technique
- This heating effect of the Er:YAG laser is theoretically 10,000 and 15,000–20,000 times higher than that of the CO2 and the Nd:YAG lasers, respectively. Since the Er:YAG laser is well absorbed by all biological tissues that contain water molecules, this laser is indicated not only for the treatment of soft tissues but also for ablation of hard tissues. The FDA approved the pulsed Er:YAG laser for hard tissue treatment such as cartilage removal and cavity preparation in 1997, unchanged for soft tissue surgery and sulcular debridement in 1999 and for osseous surgery in 2004.

Conventional technique
Conventional technique utilizes traditional instruments like scalpels and periodontal knives. Different procedures have been mentioned under the conventional frenectomy technique. These include Dieffenbach, Schuchardt, and Mathis. The most common being Dieffenbach V-plasty & Schuchardt Z-plasty.

Armamentarium
Bard-Parker handles no. 3, No. 15 blade, mosquito haemostat, su- ture material.

Procedure
Dieffenbach V-plasty
Surgical steps: The area is anesthetized by giving local anes-
thetic injection (2 % lignocaine with 1,200,000 adrenaline). After anesthesia is achieved, the frenum is held with a mosquito haemostat to its full depth. With the No. 15 blade mounted on a Bard-Parker handle, an incision is made along the upper surface of the haemostat till the entire depth of the frenum extends, using a scalpel. A similar incision is repeated on the under-surface of the haemostat so that the haemostat is detached along with the frenum tissue within its breaks. Once this is achieved, a rhomboid area exposing the deeper connective tissue fibres becomes visible. With the help of fine scissors, the deeper fibres are detached from the underlying periorientum. Periosteal scoring is done with the help of surgical blade so as to prevent the reattachment of fibers. The labial mucosa is undermined so as to permit the approximation of the edges. The bleeding is controlled by applying pressure pack.

Saturating: The diamond shaped wound is saturated using either a 4 or 5-0 silk sutures in simple interrupted fashion. Proper approximation of the margins is ensured. A periodontal dressing is placed to cover the surgical area.

Frenectomy by V-plasty may result in scar formation that could prevent the mesial movement of the central incisors. However, it is generally recommended for use in soft tissue rather than being absorbed onto the surface. The wavelength of Nd:YAG laser is at 1,064 nm and lies in the infrared range, which is invisible to the human eye. Thus, the Nd:YAG laser is used for hard tissue surgery and cavity preparation in 1997, unchanged for soft tissue surgery and sulcular debridement in 1999 and for osseous surgery in 2004.

Neodymium:YAG laser
The Nd:YAG laser has a wavelength of 1,064 nm and lies in the infrared zone like the CO2 laser. The Nd:YAG laser penetrates wa-
tner 80–90 nm which after it is at-
temated 10 % of its original strength. This produces a significant effect in soft tissue rather than being absorbed onto the surface. The wavelength of Nd:YAG laser is at 1,064 nm and lies in the infrared range, which is invisible to the human eye. Thus, the Nd:YAG laser is used for hard tissue surgery and cavity preparation in 1997, unchanged for soft tissue surgery and sulcular debridement in 1999 and for osseous surgery in 2004.

Carbon dioxide laser
The carbon dioxide laser has a wavelength of 10,000 nm. The beam of this laser falls in the infrared range and is thus invisible. This made the use of CO2 lasers awkward. Thus later on a quartz fiber incorporating a 650 nm coax-
ial He–Ne laser was used as an aiming beam in the handpiece. The CO2 laser received safety clear-
ance from FDA in 1976 for use in soft tissue surgery. With the CO2 laser there is rapid intracellular rise of temperature and pressure leading to cellular rupture and re-
lease of ‘laser plume’ (vapour and cellular debris).

The CO2 laser is readily ab-
sorbed by water. Soft tissue cons-
ts of 75 % to 90 % water, 98 % of the incident energy is converted into heat and absorbed at the tissue surface with very little scatter or penetration. Thus moist surface is essential for maximal effect. With CO2 laser no contact is made with the tissue, and no tactile feedback occurs.

Nd:YAG laser
The Nd:YAG laser is introduced in 1974 by Zakhov et al. as a solid-state laser that generates a light with a wavelength of 2,040 nm. Of all lasers emitting in the near- and mid-infrared spectral range, the absorption of the Er:YAG laser in water is the greatest because its 2,940 nm wave-
length coincides with the large ab-
sorption band for water.

The absorption coefficient of water of the Er:YAG laser is theo-
retically 10,000 and 15,000–20,000 times higher than that of the CO2 and the Nd:YAG lasers, respectively. Since the Er:YAG laser is well absorbed by all biological tissues that contain water molecules, this laser is indicated not only for the treatment of soft tissues but also for ablation of hard tissues. The FDA approved the pulsed Er:YAG laser for hard tissue treat-
ment such as cartilage removal and cavity preparation in 1997, un-

Diode lasers

The diode laser is a solid-state semiconductor laser that typically uses a combination of Gallium (Ga), Arsenide (As), and other elements such as Aluminum (Al) and Indium (In) to change electrical energy into light energy. The wavelength range is about 800–1600 nm. The laser emits in continuous wave and gated-pulse modes, and is usually operated in a contact method using a flexible fiber optic delivery system. Laser light at 800–900 nm is poorly absorbed in water, but highly absorbed in hemoglobin and other pigments (ALD 2000). Since the diode basically does not interact with dental hard tissues, the laser is an excellent soft tissue surgical laser (Romano, G. 1999), indicated for cutting and coagulating gingiva and oral mucosa, and for soft tissue curettage or submucosal debridement. The FDA approved oral soft tissue surgery in 1995 and submucosal debridement in 1998 by means of a diode laser (GaAs 810 nm). The diode laser exhibits thermal effects using the “hot-tip” effect caused by heat accumulation at the end of the fiber, and produces a relatively thick coagulation layer on the treated surface (ALD 2000). The usage is quite similar to electrosurgery. Tissue penetration of a diode laser is less than that of the Nd:YAG laser, while the rate of heat generation is higher (Rastegar S 1992), resulting in deeper coagulation and more charring on the surface compared to the Nd:YAG laser. The width of the coagulation layer was reported to be in excess of 1.0 mm in an incision of bovine oral soft tissue in vitro (White JM 2002). The advantages of diode lasers are the smaller size of the units as well as the lower financial costs.

Argon laser

The argon laser uses argon as an active medium and is fiber optically delivered in continuous wave and gated pulsed modes. This laser has two wavelength modes, 488 nm (blue) and 514 nm (bluegreen), in the spectrum of visible light. The argon laser is poorly absorbed in water and therefore does not interact with dental hard tissues. However, it is well absorbed in pigmented tissues, including hemoglobin and melanin, and in pigmented bacteria.

The argon laser was approved by the FDA for oral soft tissue surgery and curing of composite materials in 1991 and for tooth whitening in 1995. Considering the advantages of eradication of pigmented bacteria, this laser may be useful for the treatment of periodontal pockets.

Alexandrite laser

The Alexandrite laser is a solid-state laser employing a gemstone called Alexandrite, which is chromium-doped: Beryllium-Aluminum-Oxide (chrysoberyl (Cr3+; BeAl2O4) and is one of the few trichroic minerals. Rechmann & Henning first reported that the frequency-doubled Alexandrite laser (wavelength 532 nm, pulse duration 100 ns, double spikes, q-switched) could remove dental calculus in a completely selective mode without abrating the underlying enamel or cementum. The development of this laser for clinical use is widely expected due to its excellent ability for selective calculus removal from the tooth or root surface without abrating the tooth structure.

Excimer laser

Excimer lasers are lasers that use a noble-gas halide, which is unstable, to generate radiation, usually in the ultraviolet region of the spectrum. Frenzen et al. demonstrated that the ArF excimer laser, wavelength 193 nm, could effectively remove dental calculus without causing any damage to the underlying surface. The cementum surface was clean, and only a slight roughness could be observed after irradiation, supporting the use of excimer lasers for laser scaling. Folvaczky et al. have reported that the 508 nm wavelength XeCl excimer laser could effectively ablate dental calculus without thermal damages or smear layer production.

Frenectomy procedure using diode lasers Diode laser (A.R.C. Fox®) with wavelength of 810 nm was selected for the procedure. No local anesthesia was given to the patient. The frenum was stretched to visualize its extent. The diode laser was applied in a contact mode with focused beam for excision of the tissue. The ablated tissue was continuously mopped using wet gauze piece. This takes care of the charred tissue and prevents excessive thermal damage to underlying soft tissue. The tissue was laser until all the underlying muscle fibers were dissected. No sutures were placed at the end of this procedure. Patients were asked to take analgesics only if needed. Advantages of Laser over Conventional technique:

No need of local anesthesia.

Hence it’s a painless procedure.

As a result there is less patient apprehension.

Bloodless operative field, thus better visibility.

No need of periodontal dressing, therefore no patient discomfort.
